## ABSTRACT

We present new interferometric observations for 74 luminous red stars, made in the near infrared. We show that our 2.2  $\mu$ m diameters agree with other near-infrared diameter determinations (lunar occultations and interferometer's) for stars measured in common with ours. From our 'new' data we derive effective temperatures that are compared to our previous work and to comparable observations made by lunar occultations at Kitt Peak. The combined data set yields 91 luminosity II, II-III and III stars that have well-determined spectral types spanning the range from about K0 to about M8. There are 83 stars in the sample that define an approximately relationship between spectral type and effective temperature for giants with a dispersion of 192 K at each spectral type. Eight of the stars have temperatures that are roughly 750 K too low for their spectral types. These stars are not known to be at the high luminosity end of the range of stars observed and are not recognized as binary stars. At present we have no explanation for their low effective temperatures. We also show that Hipparcos parallaxes combined with our angular diameters yield linear radii precise enough to see differences in the average radius between luminosity class II and luminosity class III stars.

## I. INTRODUCTION

Measurements of the angular diameters for oxygen-rich giants and supergiants at 2.2  $\mu\text{m}$  have been a long-term goal at IOTA (the infrared Optical Telescope Array) since first fringes were obtained in late 1993. In this paper we report new visibility observations for 74 evolved stars. We felt that it was timely to publish them so that they would nearly coincide with the release of the parallax data set from Hipparcos. The combination of well-determined angular diameters with distances will lead to a large body of linear diameters for the upper right-hand part of the HR diagram. Although we have a larger body of observations than we report here, we restrict the present discussion to stars with observed average visibility levels  $V \leq 0.8$ . These stars are well enough resolved that the resulting errors in the effective temperatures are  $\sigma_T \leq 300\text{K}$ .

A complete description of the interferometer may be found in Carleton et al. (1994); the methods used to observe fringes and reduce the fringe data to uniform-disk angular diameters have been described by Dyck et al. (1996), hereafter referred to as Paper I. In Paper I we discussed the advantages of observing at 2.2  $\mu\text{m}$ , compared to both shorter and longer wavelengths. We will not repeat these discussions here, although we stress that we are generally using the fringe visibility at a single spatial frequency point to determine the uniform-disk (UD) diameter.

This method appears to be sufficiently accurate for giants and supergiants but may lead to errors for Mira variables (see, for example, Tuthill 1994); there are no known Mira variables in the present sample of stars. As an example of the accuracy of this method for characterizing the angular diameter of a star, we show our accumulated data for the M5 supergiant  $\alpha^1\text{Her}$  taken at IOTA and IRMA (see Dyck et al. 1993 for the latter) plotted in Figure 1. A simple uniform-disk visibility function, with  $\theta_{\text{UD}} = 33.2 \pm 0.8$  milliarcsec (mas), has been fitted to the data. One may see that there is no systematic departure from the UD function at spatial frequencies lower than the first zero. Beyond the first zero the observed data also fit the UD well although there may be a small amount of excess power (1-2%) that could originate in surface

structure such as spots or limb brightening. The quality of the data is not sufficiently high to be able to judge that point at the present time. Because the Uniform Disk fits this extended-atmosphere supergiant pretty well, we expect that the results for less extended luminosity class III stars will be at least as good. Thus, we feel justified in determining the angular diameter for luminosity I, II and III stars from a single observation of the visibility made at one spatial frequency point. Note also that the comparison of the IRMA and IOTA data, taken at epochs differing by about 4 years, sets a limit on the amount of variability over this timescale.

We have also compared our angular diameter measurements with those taken by other observing methods, including lunar occultations at 1.65 and 2.2 $\mu$ m and interferometry at 2.2 $\mu$ m at CERGA and at IOTA with the FLUOR beam-combination system. The references to these other diameter measurements are White & Feigman (1987) for the occultations, DiBenedetto & Rabbia (1987) and DiBenedetto & Ferluga (1990) for the CERGA observations and Perrin et al. (1997) for the FLUOR data. The comparisons are shown in Figure 2 where the agreement is seen to be good. If we fit a line to the data then the IOTA observations differ in slope by 3.8% from the other observations and have an offset at the origin of about -0.6 mas. Note that, compared to IOTA, the lunar occultation is a completely different method for obtaining angular diameters, CERGA is a different interferometer with a different method of estimating fringe visibility and FLUOR is the same interferometer but with a different beam combination scheme.

## 11. THE OBSERVATIONS

The new data are reported in Table 1, where we have given the Bright Star Catalogue (Hoffleit 1982) number, a common name or other identifier, the date of the observation (as year-month-day), the projected interferometer baseline (in m), the visibility and the uniform disk angular diameter (in mas) and an associated error (also in mas). As we reported in Paper 1, we have assigned an error to the visibility of  $\pm 0.05$ , based upon our experience with the scatter in visibility for the same star over different nights.

This error and the visibility were used to compute the error in the UD diameter. In Table 2 we have

converted the UD diameters to Rosseland mean diameters, using the relationship  $\theta_R = 1.022\theta_{UD}$ , adopted from the paper by Scholz & Takeda (1987) (see our Paper I for a discussion). Effective temperatures were computed from these Rosseland mean diameters and bolometric fluxes estimated from broad-band photometry. Note that we have not computed effective temperatures for all stars reported in Table 1. Rather, we have restricted the sample to those stars that we judge to have well-determined spectral types; references to the sources for these spectral types are given in Table 2. We also included earlier observations from Paper 1, bringing the total number of stars with effective temperature estimates to 70. Where there were overlapping data, we have averaged the UD diameters together, weighted by the error.

Random errors in the effective temperatures were computed by assuming an uncertainty of 15% in the bolometric flux (arising from errors in the absolute calibration, errors in the reddening estimate and variability) and the computed error in the UD diameter listed in Table 2. The interested reader should consult Paper 1 for details of the error estimates for the bolometric flux.

## 11. 1) DISCUSSION

### 1. *Effective Temperatures*

The effective temperatures for luminosity classes I, II-III and III have been plotted in Figure 3, where we have plotted only those stars for which the error in the temperature was  $\leq 300\text{K}$ . This resulted in 60 stars. We have also included the available occultation data from Ridgway et al. (1980) supplemented by a few additional stars reported in Paper 1. We have not replotted the stars observed at CERGA since they overlap almost completely with the IOTA observations. The total number of effective temperatures determined from occultation measurements is 31, bringing the total number plotted in Figure 3 to 91 stars. This is nearly 50% more stars than were reported in Paper 1.

One may notice three general features in the figure. First, there is a uniform mix of IOTA interferometric and occultation temperatures. Each data set appears to cover the band defined by the other with no systematic separation. This agrees with the conclusions given in Paper I. Second, all but 8 of the

stars are concentrated at the upper part of the distribution. The eight discordant stars form a parallel sequence offset by about 850K to cooler temperatures from the average of the remaining 83 stars. Finally, at the scale shown in the figure, there is a linear decrease of temperature over the range of spectral types from G8 to M8.

Because we have mixed together luminosity classes II and III it is of interest to determine whether the eight discordant stars in Figure 3 have luminosities systematically higher than the remainder of the stars. One might anticipate this effect based upon our previous result (Paper 1) showing that supergiants have systematically lower temperatures than their giant counterparts at the same spectral type. The eight stars under discussion here are  $\nu$  Leo,  $\gamma^1$  Leo, 75 Tau, 61 Leo, 46 Leo, 111175176, F1 Ser and Z UMa, all classified as luminosity class III. Two of the eight are known to be members of double systems, which could produce the observed effect, but the other stars appear to be single.

If we assume that the roughly linear relationship between spectral type and effective temperature shown in the figure is, in fact, correct, then we may determine an equation that will describe the temperature over this range of spectral types. A linear regression to all data except the eight discordant

$$T_{eff} = -106ST + 4580 \text{ K},$$

stars results in the following

where the index ST has possible values -2,...,0,...,5,6,...8 corresponding to spectral classes G8,...,K0,...,K5,M0,...,M8. The regression for the 83 stars yields a standard error for a single estimate of temperature of  $\pm 192$  K. If some other functional form better expresses the relationship between the spectral type and effective temperature for giants, then this error is an upper limit to the average dispersion at each spectral class. We have shown this regression in Figure 3 for comparison to the observed data.

The principal source of observational error for the effective temperatures is the uncertainty assumed for the bolometric flux density and not the measured angular diameter. To make a significant

improvement upon the effective temperatures for the future will probably require simultaneous observations of flux and diameter along with very precise absolute calibrations and reddening corrections.

## 2. *Stellar Radii*

We have also searched the Hipparcos database at SIMBAD to find stars in our observed sample that have had accurate parallax determinations. Fewer than a half dozen of the stars listed in ~'able 2 have parallaxes that are less than  $3\sigma$  above the measurement errors. We have isolated stars classified luminosity class II or II-III from those classified as luminosity class III. Data from these two groups have been plotted in Figure 4 as stellar radius (in Solar units) versus effective temperature, where class I and II-III stars are shown as open boxes (D) and class III stars are shown as filled diamonds ( $\blacklozenge$ ). One may see that there is a clear separation between the two luminosity classes with the class II and II-III stars being larger than the class III stars. Around an effective temperature of 3500 K the higher luminosity stars have approximately a factor of two larger radius, on the average, than do the lower luminosity stars.

The principal source of error in Figure 4 is still the error in the parallax. With increased precision in these measurements it should be possible to establish quantitative values of radius corresponding to subtle spectroscopic luminosity differences. In fact, it is this limitation in establishing the distance to our sample of stars that prevents us from constructing an H-R Diagram with the data at hand. While the parallaxes are often 5-100 results, a level of precision that allows us to see gross luminosity differences readily, the effect of computing luminosity is to increase the relative error by a factor of two (since distance enters as the second power). This yields an H-R diagram that is not even qualitatively useful.

This research has made use of the SIMBAD database, operated by the CDS, Strasbourg, France. HMD acknowledges support from NSF grant AST-958 129 while he was at the University of Wyoming. GTvB was supported while he was a student at the University of Wyoming by a grant from the PASS Center.

Table 1. The new visibility and uniform disk diameter data.

## FIGURE CAPTIONS

Figure 1. A plot of the  $2.2\mu\text{m}$  visibility data for the MS supergiant  $\alpha^1$  Her with a Uniform Disk visibility function plotted for comparison. Note that there is no apparent systematic difference between the observations and the simple model for this atmospherically-extended star. This is used as justification for deriving the angular diameter for giants and supergiants from a single observation of the visibility at one spatial frequency point.

Figure 2. A comparison of the uniform disk angular diameter (UDID) observations made at IOTA with those obtained by other means. Sources for the other measurements are discussed in the text. The line shown in the figure is the best fit to the data and is also discussed in the text.

Figure 3. A plot of the effective temperature versus spectral type for luminosity classes II, III and III stars, comparing the results of lunar occultation observations with those from interferometry, all made at near-infrared wavelengths. The dashed line is a linear regression discussed in the text.

Figure 4. A plot of stellar radius as a function of effective temperature. Note that luminosity class II and II-III stars are systematically larger than luminosity class III stars at a given effective temperature.
